The Japanese company **Sony** was the first to successfully develop lithium-ion batteries as a new green battery to replace lead-acid and nickel-metal hydride batteries. Negative and positive electrodes, electrolytes, separators, and external packaging make up the majority of lithium-ion batteries.

Through procedures like **lamination and winding**, the positive electrode, negative electrode, and separator are shaped into a square or circular form. To create a lithium-ion battery, an electrolyte is injected into the spaces and sealed with steel, aluminum, or other shell materials.

When a lithium-ion battery is discharged, the basic mechanism is for the lithium ions to leave the positive electrode, move through the electrolyte, and become embedded in the negative electrode. This causes the electrons to move in the external circuit, which generates external power.
